A Note on the Hartley-Rao Variance Estimator

Phillip S. Kott

The Hartley-Rao variance formula was designed to estimate the randomization variance of a Horvitz-Thompson estimator given a systematic probability proportional to size sample from a randomly ordered large population. Using an underappreciated formulation of this variance estimator, one can see that the Hartley-Rao variance estimator is unbiased under a model with a particular error structure given any sample. Moreover, even with a more general error structure, this variance estimator remains nearly model unbiased for a large sample and relatively larger population under mild conditions. A discussion follows concerning an extension of Hartley-Rao variance estimation to linear calibration estimators.

Key words: Goodman-Kish design; Sampford design; finite population correction factor; relatively larger population; linear calibration estimator.

1. Introduction

Let \( \bar{Y} = \sum_{i \in U} y_i / N \) denote a population mean, where \( U \) is a population of \( N \) units. The Horvitz-Thompson estimator for \( \bar{Y} \) is \( t_{HT} = N^{-1} \sum y_i / \pi_i \), where \( S \) is a sample of fixed size \( n \), and \( \pi_i \) is the selection probability of unit \( i \). It is well-known that \( t_{HT} \) is randomization unbiased; that is, unbiased with respect to the random sampling mechanism.

Suppose the units in the sample were drawn using a Goodman-Kish design, i.e., systematically from a randomly ordered list with arbitrary probabilities of selection (see Brewer and Hanif 1983, p. 22). Hartley and Rao (1962) offer the following estimator for the randomization variance of \( t_{HT} \):

\[
v_{HR} = 2^{-1} N^{-2} [(n - 1)]^{-1} \sum_{i \in S} \sum_{j \in S} \left( 1 - \pi_i - \pi_j + \sum_{k \in U} \pi_i \pi_j \pi_k / n \right) \left( \frac{y_i}{\pi_i} - \frac{y_j}{\pi_j} \right)^2
\]

It is proven there that when the population is large compared to the sample, \( v_{HR} \) is nearly randomization unbiased. Formally, if \( \max \{ \pi_i \} < c \), and \( c \) is \( O(N^{-1}) \), then the randomization bias of \( v_{HR} \) is \( O(N^{-2}) \).

Asok and Sukhatme (1976) effectively show that \( v_{HR} \) has the same property under the Sampford sampling design. Moreover, the authors prove that using the Sampford design has, if anything, slightly less randomization variance (ignoring \( O(N^{-3}) \) terms) than the Goodman-Kish design. A short description of the Sampford design follows: Select unit \( i \) with probability proportional to \( \pi_i \) on the first of \( n \) draws and probability proportional to

\[
\pi_i/(1 - \pi_i), \text{ with replacement, on the subsequent } n - 1 \text{ draws; if any unit is selected more than once, reject the sample and begin again. Brewer and Hanif (1983) show that the Sampford design (which they called the Rao-Sampford design) is equivalent to many popular unequal probability schemes when } n = 2.
\]

Following Cumberland and Royall (1981), observe that the right-hand side of Equation (1) can be put in this more convenient form:

\[
v_{HR} = N^{-2}\left[n/(n - 1)\right] \sum_{i \in S} \left(1 - \pi_i - \sum_{k \in e_i} \pi_k/n + \sum_{k \in \bar{e}} \pi_k^2/n\right) \\
\times \left[\pi_i/n - n^{-1} \sum_{j \in S} \pi_j\right]^2
\]

(2)

Although not new, this formulation of the Hartley-Rao variance estimator is not as well-known as it should be. The expression \[1/n^2 \sum_{i \in S} \pi_i^2/n + \sum_{i \in \bar{e}} \pi_i^2/n,\] which collapses to \[1 - n/N\] in Equation (2) when all the \(\pi_i\) are equal, can be viewed as a term-wise finite population correction factor.

Suppose the \(y_i\) satisfy the model

\[
y_i = \beta x_i + x_i e_i
\]

(3)

where the \(x_i\) are proportional to the \(\pi_i\), and the \(e_i\) are uncorrelated random variables with mean zero given \(x_i\), then \(t_{HT}\) is a model unbiased estimator for \(\bar{Y}\) in the sense that \(E_{\pi}(t_{HT} - \bar{Y}) = 0\) (see, for example, Brewer 1963). Cumberland and Royall (1981) show that \(v_{HR}\) is a model unbiased estimator for the model variance of \(t_{HT}\) when the \(e_i\) have a common variance no matter what the corresponding \(x_i\). As we shall see, \(v_{HR}\) remains a nearly model unbiased variance estimator under certain conditions when the \(e_i\) are uncorrelated but have unequal variances. The model-based properties of \(v_{HR}\) do not require either a Goodman-Kish or Sampford sampling design.

One restriction on the population necessary for any without replacement probability-proportional-to-\(x_i\) sampling scheme is that no \(x_i\) be larger than \(\sum_{j \in S} x_j/n\). We assume that the population under study has this property.

2. Cumberland and Royall’s Model-Based Result

Let the model variance of \(e_i\) in Equation (3) be \(v_i\). Since \(n\) is fixed, \(\pi_i = nx_i/(N\bar{X})\), where \(N\bar{X} = \sum_{i \in S} x_i\). The model variance of \(t_{HT}\) is

\[
E_{e_i}[t_{HT} - \bar{Y}]^2 = E_{e_i}\left\{N^{-1}\sum_{i \in S} (\beta x_i + x_i e_i)/\pi_i - N^{-1}\sum_{i \in \bar{e}} (\beta x_i + x_i e_i)\right\}^2
\]

\[
= N^{-2}E_{e_i}\left\{\sum_{i \in S} x_i e_i/\pi_i - \sum_{i \in \bar{e}} x_i e_i\right\}^2
\]
Kott: A Note on the Hartley-Rao Variance Estimator

\[ \bar{x}_i = \frac{1}{n} \sum_{i \in S} x_i \]

\[ \bar{v}_i = \frac{1}{n} \sum_{i \in S} v_i \]

\[ \bar{x}_i - \bar{v}_i = \frac{1}{n} \sum_{i \in S} (x_i - v_i) \]

\[ = (\bar{x}/n)^2 \mathbb{E}_e \left\{ \left( \sum_{i \in S} \epsilon_i - \sum_{i \in U} \pi_i \epsilon_i \right)^2 \right\} \]

\[ = (\bar{x}/n)^2 \mathbb{E}_e \left\{ \left( \sum_{i \in S} \epsilon_i \right)^2 - 2 \mathbb{E}_e \left[ \sum_{i \in S} \epsilon_i \sum_{i \in U} \pi_i \epsilon_i \right] + \mathbb{E}_e \left[ \sum_{i \in U} \pi_i \epsilon_i \right]^2 \right\} \]

\[ = (\bar{x}/n)^2 \left( \sum_{i \in S} \epsilon_i - 2 \sum_{i \in S} \pi_i v_i + \sum_{i \in U} \pi_i^2 v_i \right) \]

(4)

while the model expectation of \( v_{HR} \) is

\[ E_e(v_{HR}) = \mathbb{E}_e \left\{ N^{-2}(n/(n-1)) \sum_{i \in S} \left( 1 - \pi_i - \sum_{k \in S} \pi_k/n + \sum_{k \in U} \pi_k^2/n \right) \right\} \times \left( \frac{\beta x_i + x_i e_i}{\pi_i} - \left[ n^{-1} \sum_{j \in S} (\beta x_j + x_j e_j)/\pi_j \right] \right)^2 \]

\[ = N^{-2}(n/(n-1)) \sum_{i \in S} \left( 1 - \pi_i - \sum_{k \in S} \pi_k/n + \sum_{k \in U} \pi_k^2/n \right) \times \mathbb{E}_e \left\{ \left( x_i e_i/\pi_i - n^{-1} \sum_{j \in S} x_j e_j/\pi_j \right)^2 \right\} \]

\[ = (\bar{x}/n)^2 \left( n/(n-1) \right) \left( 1 - \sum_{j \in S} \pi_j/n + \sum_{j \in U} \pi_j^2/n - \pi_i \right) \times \mathbb{E}_e \left\{ \left( e_i - n^{-1} \sum_{j \in S} e_j \right)^2 \right\} \]

\[ = (\bar{x}/n)^2 \left( n/(n-1) \right) \left( 1 - \sum_{j \in S} \pi_j/n + \sum_{j \in U} \pi_j^2/n - \pi_i \right) \times (v_i - 2v_i/n + v_0/n) \]

(5)

where \( v_0 = \sum_{j \in U} v_j/n \).

When all the \( v_i \) in the population are equal to \( v_0 \), the right-hand sides of Equations (4) and (5) are both
\[ V_0 = \left( \frac{\bar{x}^2}{n} \right) \left( 1 - 2 \sum_{i=3} \pi_i/n + \sum_{i=1} \pi_i^2/n \right) v_0 \]

Thus, when the model in Equation (3) holds, and the \( e_i \) have a common variance, \( v_{HR} \) is an unbiased estimator of the model variance of \( t_{HT} \). Note that this is true no matter how the sample is drawn.

Even when the \( v_i \) are not all equal, \( v_{HR} \) may be almost model unbiased in some sense. For example, when \( \max \{ \pi_i \} < c \), where \( c = O(N^{-1}) \), the model bias of \( v_{HR} \) is \( O(N^{-1}) \) since both the model variance of \( t_{HT} \) (from Equation (4)) and the model expectation of \( v_{HR} \) (from Equation (5)) are

\[ V_n = \left( \frac{\bar{x}^2}{n} \right) \sum_{i=3} v_i + O(N^{-1}) \]

Ignoring \( O(N^{-1}) \) terms, but not \( O(n^{-1}) \) terms, is equivalent to completely ignoring finite population correction.

3. Large-Sample Results

Isaki and Fuller (1982) formulate a more standard asymptotic theory where the sample size, rather than the population size, is assumed to be large. Of course, \( N \) must be larger than \( n \) in this framework, but \( 1/N \) need not be any smaller than \( O(1/n) \); that is to say, \( n/N \) can converge to a positive constant as \( n \) grows arbitrarily large.

Isaki and Fuller provide sufficient conditions on the sampling design and population for

\[ \Sigma_{xj} \mu_j - \Sigma_{xi} \pi_x \mu_x/n \quad \text{and} \quad \Sigma_{xj} \nu_j - \Sigma_{xi} \pi_x \nu_x/n \]

to be \( O_p(n^{-1/2}) \), while \( \Sigma_{xi} \mu_x/N = O(1) \), and \( \Sigma_{xj} \mu_j/n \) and \( \Sigma_{xj} \nu_j/n \) are \( O_p(1) \). Under these conditions, it is not hard to see that the model variance of \( t_{HT} \) is itself \( O_p(1/n) \). Moreover, the model variance of \( t_{HT} \) and the model expectation of \( v_{HR} \) are both

\[ V_n = \left( \frac{\bar{x}^2}{n} \right) \sum_{i=3} (1 - \pi_i)v_i + O_p(n^{-3/2}) \]

since \( -\Sigma_{xj} \pi_j v_j/n + \Sigma_{xj} \pi_j^2 v_j/n \) in Equation (4) and \( -\Sigma_{xj} \pi_j^2/n + \Sigma_{xj} \pi_j^2/n \) in Equation (5) are \( O_p(n^{-1/2}) \). Recall that \( \pi_i = nx_i/\Sigma_{x}x_i \).

Note that although we are concerned here with model bias, we are invoking the large-sample properties of the sample design. We are not, however, averaging over all possible samples in this context as randomization-based theory does. Moreover, we will not call \( v_{HR} \) "nearly model unbiased" unless its model bias - the difference between the model variance of \( t_{HT} \) and model expectation of \( v_{HR} \) - is \( O_p(n^{-2}) \).

Suppose now that \( n \) is large and \( N \) is relatively larger, but not so much so that finite population correction can be completely ignored. This often happens in practice; \( n \) is large enough (say \( n \approx 50 \)) for conventional asymptotic properties to have relevance; \( N \) is larger still (say \( N \approx 250 \)), but finite population correction can have an effect on variance estimation.

Following Kott (1990), we formalize the notion of a relatively large population (compared to a large sample) by assuming \( 1/N \) is \( O(n^{-3/2}) \) rather than \( O(1/n) \). If
max(\(\pi_i = nx_i/(N\bar{x})\)) < c, where c is now \(O(n/N) = O(n^{-1/2})\), then the sampling design and population are such that both \(-\Sigma_S \pi_i/n + \Sigma_U \pi_i^2/n\) and \(-\Sigma_S \pi_i \epsilon_i/n + \Sigma_U \pi_i^2 \epsilon_i/n\) are \(O_p(n^{-1})\) under mild conditions we assume to hold. As a consequence, the model bias of \(v_{HR}\) is \(O_p(n^{-2})\); that is to say, \(v_{HR}\) is nearly unbiased under the model in Equation (3) with uncorrelated errors when the sample is large and the population relatively larger.

4. Discussion

Although neither a Goodman-Kish nor a Sampford sampling design is necessary for \(v_{HR}\) to have desirable model-based properties, the use of one of these selection schemes coupled with mild restrictions on the population is sufficient. Moreover, under either of these two designs, \(v_{HR}\) has an \(O(n^{-2})\) bias as an estimator for the randomization variance of \(t_{HR}\) when \(\max\{\pi_i\} < c\) and \(c = O(N^{-1})\).

Like Cumberland and Royall (1981), we have focused on a formula that estimates both the randomization and model variance of the Horvitz-Thompson estimator well under Goodman-Kish or Sampford sampling. The simultaneous variance estimator, \(v_{HR}\) in Equation (2), differs from the formulation in Brewer and Donadio (2003) (combining its Equations (16) and (18)) that attempts to estimate the model expectation of the randomization variance of the Horvitz-Thompson when all the \(\epsilon_i\) are equal.

A word of caution is in order. Goodman-Kish and Sampford sampling are often used in practice within tightly-defined design strata. When the sample size within each stratum is small, the large-sample model-based results of the last section have little relevance. Moreover, the advantage of the Cumberland-Royall formulation \(v_{HR}\) in Equation (2) over Equation (1) is muted.

Recently, however, the National Agricultural Statistics Service (NASS) has been using unequal probability designs either without strata or within very large strata (see Kott and Bailey 2000). The estimators employed by NASS have linear calibration form. In the context of estimating \(\bar{Y}\), such an estimator can be rendered as \(t_{LC} = N^{-1}\sum_{i \in U} w_i y_i\), where the calibration weight for unit \(i\) is \(w_i = (1/\pi_i)(1 + (\sum_S \epsilon_i - \Sigma_S \epsilon_i/\pi_i)(\Sigma_S h^T_k x_k/\pi_i)^{-1} h_k^T)\), and \(x_k\) and \(h_k\) are row vectors of the same dimension.

Estevao and Särndal (2000) discuss conditions under which \(t_{LC}\) has good model-assuming \(y_i = x_i \beta + \epsilon_i\) with \(E(\epsilon_i|x_i) = 0\) - and randomization-based properties. Under those conditions, and given either a Goodman-Kish or Sampford sample, a reasonable estimator for the randomization mean squared error of \(t_{LC}\) is

\[
v_{HR} = N^{-2}[n/(n-1)]\sum_{i \in S} \left(1 - \pi_i - \sum_{k \in S} \pi_k/n + \sum_{k \in U} \pi_k^2/n\right) \times \left[w_i e_i - \left[n^{-1}\sum_{j \in S} w_j e_j\right]\right]^2 \tag{6}
\]

where \(e_i = y_i - x_i (\Sigma_S h^T_k x_k/\pi_i)^{-1} \Sigma_S h^T_k y_k/\pi_i\). Following Särndal, Swensson, and Wretman (1989), this formulation effectively replaces \(y_i/\pi_i\) in Equation (2) by \(w_i e_i\) for model-based reasons.
Using arguments like those made earlier, \( v_{HR} \) in Equation (6) is also a nearly unbiased estimator for the model variance of \( t_{LC} \) under mild conditions when the \( e_i \) are uncorrelated, the sample size is large, and the population size is relatively larger.

When a component of the vector \( h_k \), or some linear combination of components, is constant across the \( k \) (formally, \( \mathbf{h}_g = 1 \) for some column vector \( g \)), the \( \sum s w_i e_i \) term in Equation (6) is equal to zero. To see why, first note that \( \sum s w_i e_i = \sum s e_i / \pi_i \) by the way \( e_i \) is defined. When \( \mathbf{h}_g = \mathbf{g}' \mathbf{h}_i = 1 \), we have

\[
\sum e_i / \pi_i = \sum y_i / \pi_i - \sum (x_i / \pi_i) \left( \sum h'_i x_k / \pi_k \right)^{-1} \sum h'_i y_k / \pi_k
\]

\[
= \sum y_i / \pi_i - \sum \left( g' h'_i x_k / \pi_i \right) \left( \sum h'_i x_k / \pi_k \right)^{-1} \sum h'_i y_k / \pi_k
\]

\[
= \sum y_i / \pi_i - \sum g' h'_i y_k / \pi_k = 0
\]

The finite population correction factors \( 1 - \pi_i - \sum s \pi_k / n + \sum u \pi_k^2 / n \) in Equation (6) can be ignored in practice when \( \max \{ \pi_i \mid i \in S \} \) and \( \sum u \pi_k^2 / n \) are ignorably small. Both the randomization and model-based properties of \( v_{HR} \) depend on \( n \) being large. From a model-based point of view, even under ideal conditions (\( \text{Var}(e_i | x_i) \propto \pi_i^2 \)), \( e_i \) is only equal to \( e_i \) asymptotically. Similarly, from a randomization-based viewpoint, \( w_i \) only need converge to \( 1/\pi_i \) as the sample size grows arbitrarily large. See Kott (2005) for a discussion of the relative speed of the asymptotics.
